Lecture #8: More on Functions

Another Recursion Problem: Counting Partitions

- I'd like to know the number of distinct ways of expressing an integer as a sum of positive integer "parts."
- teger parts to some given value: To make things more interesting, let's also limit the size of the in-

def num_partitions(n, k): """Number of distinct ways to express N as a sum of positive integers each of which is \leftarrow K, where K > 0. (The empty sum is 0.)"""

Example:

xo6 = 3 + 3= 2+1+1+1+1 = 1+1+1+1+1+1= 2+2+1+1= 2 + 2 + 2=3+1+1+1= 3 + 2 + 1

so num_partitions(6, 3) is 7.

Identifying the Problem in the Problem

Last modified: Sun Feb 19 15:44:29 2017

- Again, consider num_partitions(6, 3)
- rest won't. Some partitions will contain the maximum size integer, 3, and the
- Those that do contain 3 then have various ways to partition the remaining 3.

3 + + + 3 + + 1 + 1 + 1

 While those that do not contain 3 partition 6 using integers no larger than 2:

These observation generalize, and lead immediately to a solution.

Counting Partitions: Code (III)

else: if n < 0: elif k == 1 or n <= return 1 return 0

Last modified: Sun Feb 19 15:44:29 2017 CS61A: Lecture #8 6

Counting Partitions: Code (IV)

```
def num_partitions(n, k):
    """Number of distinct ways to express N>=0 as a sum of positive
    integers each of which is <= K, where K > 0. (The empty sum is 0.)"""
    if n < 0:
        return 0
    elif k == 1 or n <= 1:
        return 1
    else:
        return num_partitions(n - k, k) + num_partitions(n, k - 1)</pre>
```

Functions and Data

- We tend to think of functions as simply doing or computing something with data.
- In fact, they can also represent or contain data themselves
- Trivial example:

```
>>> def const(n):
... return lambda: n
>>> x, y = const(5), const(11)
>>> print(x(), y())
5,11
```

 The functions returned by const contain pointers to the local frames created when const was called, which in turn contain copies of the argument values (5 and 11).

CS61A: Lecture #8

CS61A: Lecture #8 8

Functions and Data (II)

Last modified: Sun Feb 19 15:44:29 2017

We can get a bit fancier:

```
>>> def cons(left, right):
... return lambda which: left if which else right
>>> P = cons("value", 42)
>>> print(P(True), P(False)
>>> L = cons(1, cons(2, cons(3, None)))
>>> print(L(True), L(False)(True), L(False)(True),
... L(False)(False)(False))
1 2 3 None
```

(See the chain example at the end of Lecture #4.)

So, in effect, values returned by cons are lists of values.

The Pair Abstraction

- \bullet However, writing $P({\tt True})$ for "the left part of P" is not the clearest code one could imagine.
- Better to express the programmer's intent:

```
>>> def cons(left, right):
...     return lambda which: left if which else right
>>> def left(pair): return pair(True)
>>> def right(pair): return pair(False)
>>> P = cons("walue", 42)
>>> print(left(P), right(P))
value 42
```

- Together, these three functions define a data type.
- The data (pairs) are represented by functions returned by cons.
- left and right are the basic operations on the data type.
- If we use these cons, left, and right and three functions and ignore the fact that cons really produces a function rather than a pair, we are obeying the abstraction barrier.

Data Abstraction Philosophy

Last modified: Sun Feb 19 15:44:29 2017

- In the old days, one described programs as hierarchies of actions: procedural decomposition.
- Starting in the 1970's, emphasis moved to the data that the functions operate on.
- An abstract data type (ADT) (like the pair abstraction) represents some kind of thing and the operations upon it.
- Instances of the type are often generically called objects.
- We can usefully organize our programs around the ADTs in them.
- For each type, we define an interface that describes for users ("clients") of that type of data what operations are available.
- Typically, the interface consists of functions.
- The collection of specifications (syntactic and semantic—see lecture #6) constitute a *specification of the type*.
- We call ADTs abstract because clients ideally need not know internals.

CS61A: Lecture #8 11

Rational Numbers

The book uses "rational number" as an example of an ADT:

```
def make_rat(n, d):
    """The rational number n/d, assuming n, d are integers, d!=0"""
def add_rat(x, y):
    """The sum of rational numbers x and y."""
def mul_rat(x, y):
    """The product of rational numbers x and y."""
def numer(x):
    """The numerator of rational number r."""
```

- \bullet These definitions pretend that $x,\ y$, and r really are rational numbers.
- \bullet But from this point of view, the definitioins of \mathtt{numer} and \mathtt{denom} are problematic. Why?

Last modified: Sun Feb 19 15:44:29 2017 C561A: Lecture #8 12

A Better Specification

- ullet Problem is that "the numerator (denominator) of r" is not well-defined for a rational number.
- If make rat really produced rational numbers, then make $\operatorname{rat}(2,\ 4)$ and make $\operatorname{rat}(1,\ 2)$ ought to be identical. So should make $\operatorname{rat}(1,\ -1)$ and make $\operatorname{rat}(-1,\ 1)$.

```
So a better specification would be
                                                                                                                                     \label{eq:def_numer} \texttt{def numer}(\mathbf{r}): """The numerator of rational number r in lowest terms."""
                                                                          def denom(r):
"""The denominator of rational number \boldsymbol{r} in lowest terms Always positive."""
```

```

Changing Representations

- It's cute that functions can represent pairs (or anything else, for that matter), but it's not a particularly efficient use of the them.
- Suppose that we instead decide to use Python's tuples. What changes?

```
def left(pair): return pair[0]
def right(pair): return pair[1]
                                                return (left, right)
                                                                       cons(left, right)
```

Crucial Observation: Nothing else changes!
